

Decision Curve Analysis

Net benefit = $TP/N - FP/N \times (pt / (1-pt))$, where pt is the threshold probability.

Treat-all and treat-none are reference strategies (lighter grey).

Lower panel: percentage of the cohort each model classifies as high risk at that threshold. Where a line reaches 0%, no patient is treated and net benefit is necessarily 0 rather than meaningfully worse than the alternatives.

Net benefit was computed over thresholds of 1-99%; the axis is shown to 90%, beyond which no model classifies any patient as high risk and all curves are identically 0.
